Chapter 4

Experimental design Design for predictive models Predictive Models in microbiology depending Microbiology Depending on environmental variables Environmental Variables

Polina Gaindrik, Jonas Pleyer, Daniel Heger, and Christian Fleck

Abstract

The aim of predictive microbiology is the provision of tools and methods for predicting the growth, survival, and death of microorganisms in different food matrices under a range of environmental conditions. The parametrized mathematical models need to be calibrated using dedicated experimental data. In order to efficiently plan experiments, model-based experimental design is used. In this chapter, we explain model-based experimental design and provide step-by-step instructions for finding the optimal design using the well-known Baranyi-Roberts growth model as an example. We provide the Python software *eDPM* for Ordinary Differential Equation (ODE)-based models, such that the reader can apply model-based experimental design in their research context.

Keywords Optimal experimental design, Parameter estimation, Fisher information matrix (FIM), Identifiability, Uncertainty

1 Introduction

Mathematical modeling is widely used to describe, understand, and predict the behavior of living systems. In particular, in the field of predictive microbiology, one can find a large variety of works that dwell on building models of different levels of complexity controlled by model parameters, e.g., to describe bacterial growth [1]. Predictive microbiology is a subfield of food microbiology based on the premise that the behavior of microorganisms can be described

by the use of mathematical models accounting for the effects of various factors such as temperature, pH, water activity, and the presence of preservatives, on the growth and survival of microorganisms. These models can then be used to predict the behavior of microorganisms under different conditions and to evaluate the effectiveness of various control measures, such as refrigeration, heat treatment, or the addition of preservatives. Predictive microbiology has many applications in food safety, as it can be used to assess the risk of foodborne illness, to design safe food processing and storage practices, and to develop new food products with extended shelf-lifeshelf life. For successful predictions, it is essential that the model parameters can be estimated from experimental data. However, due to measurement noise the estimates are accompanied by some uncertainties. That gives rise to a set of important questions: Can all parameters of the given model structure be estimated? What should be measured and when? What are the confidence intervals for the parameters? How can the experimental effort be minimized? Answering these questions equates to finding the optimal experimental design (OED). This results in defining optimized experimental conditions and/or measurement times, which allows for a reduction of the experimental load without loss of information [2, 3]. In general, experimental design can be also also be used for model discrimination [4, 5]. However, in this chapter we focus on the design procedure developed to increase parameter estimation precision. Comprehensive reviews on can be found here: [6-9].

The whole parameter estimation process starts with choosing a model structure and defining observable quantities which the researcher is interested in (see Fig. 1). Once this is chosen, a first parameter set is selected based on literature review or prior data. In order to fine-tune the experimental design setup to the given use caseuse case, we need to choose an objective function that will be optimized. Depending on the goal, a researcher faces an important choice; which: Which of the several sometimes contradicting objectives should be chosen for a particular case? For example, is it more desirable to have precise knowledge in a

chosen set of parameters and less information about the remaining ones? What is the best balance between experimental effort and precision? Using multi-objective approaches, some attempts were made to answer these questions and to improve the experimental design by combining several objectives [10, 11]. For models that depend on external cues like temperature, it is a priori a priori not clear whether constant variable conditions are more efficient for parameter estimation [12, 13]. Using the initial guess of parameters, a first OED is determined taking into account specific constraints, such as a maximum number of measurements, measurement times, etc. Next, the designed experiments need to be performed, and this data results into a new estimation of the parameters. If the confidence intervals of the parameters are sufficiently small, the scheme ends, otherwise, otherwise, one uses the new estimates as the starting point for the next experimental design. The process can be repeated several times to increase the precision of the parameter estimates until the desired accuracy is achieved. In order to test the scheme, one can also perform numerical experiments and obtain *in silico* in silico data.

2 Materials

There are several software packages available for model-based experimental design [14–16]. These packages comprise numerous tools and consequently require some time to understand how to use them. We developed eDPM (Experimental Design for Predictive Microbiology), which focuses on ease of use. It is a set of tools to calculate the sensitivity and Fisher information matrix and do parameter space exploration in order to find optimal results. We require a working installation of the popular scripting language Python ≥ 3.7 [17]. For installation instructions, please refer to the website python.org. In addition, we expect users to be able to write, execute, and display output of scripts. This tutorial can also be followed using Jupyter Notebook [18]. Users can obtain it by installing eDPM from pypi.org. The python website has guides for installing packages packaging.python.org/. Most Unix-Based systems (e.g., GNU/Linux) and Mac-OS can use pip

pip install eDPM

or conda to install the desired package.

conda install eDPM

The documentation of the package is continuously updated. After the installation of the package is complete, we open a file with a text editor of choice and simply start writing code. We begin by writing a so-called she-bang which that is responsible to signalize that this file is to be executed with python. Afterwards Afterward, we import the needed packages. This will serve as the starting point

```
1 #!/usr/bin/env python3
2
3 import numpy as np
4 from eDPM import *
```

Code Sample 1: Import statements to use eDPM

for our script.

In the following, we will append more code to it and utilize the methods developed in *eDPM* [19]. The Code Samples containing line numbers correspond to one script that defines the system subjected to optimization. The line numbers indicate the order of the code.

3 Methods

3.1 Model Formulation

3.1.1 Theory

As a starting point, it is necessary to define the mathematical model. We restrict our discussion to biological systems which that can be described by a system of Ordinary Differential Equations:

$$\begin{cases} \dot{\mathbf{x}}(t) = \mathbf{f}(t, \mathbf{x}, \mathbf{u}, \mathbf{p}) \\ \mathbf{x}(t_0) = \mathbf{x}_0. \end{cases}$$
 (1)

Here $\mathbf{x} = (x_1, x_2, ..., x_n)$ is a vector of state variables of the system with initial condition \mathbf{x}_0 , t is a time, \mathbf{u} is a vector of externally controlled inputs into the system (e.g., supply of glucose or external temperature), and \mathbf{p} are the parameters of the system. We assume that a subset of the parameters \mathbf{p} is unknown and should be estimated from data. Predominantly, the state variables cannot be directly observed, but rather the observables are functions of the state variables:

$$\mathbf{y}(t) = \mathbf{g}(t, \mathbf{x}(t), \mathbf{u}, \mathbf{p}) + \epsilon(t), \tag{2}$$

where the function **g** is an observation or output function, and ϵ is a measurement noise. The observational noise is often assumed to be an independently distributed Gaussian noise with zero mean and variance σ^2 : $\epsilon(t) \sim N(0, \sigma^2)$, $\forall t$.

In this tutorial, we demonstrate the usage of experimental design on the widely employed mathematical model developed by Baranyi and Roberts [20], which was devised to describe bacterial growth. The model introduces two state variables $\mathbf{x} = (x_1, x_2)$, where $x_1(t)$ denotes the cell concentration of a bacterial population at the time t and $x_2(t)$ is the quantity defining the proportion of the growth rate specified by the environment, e.g., a limiting nutrient critical for bacterial growth:

$$\begin{cases} \dot{x}_1(t) = f_1(x_1, x_2) = \frac{x_2(t)}{x_2(t)+1} \mu^{\max} \left(1 - \frac{x_1(t)}{x_1^{\max}}\right) x_1(t) \\ \dot{x}_2(t) = f_2(x_1, x_2) = \mu^{\max} x_2(t). \end{cases}$$
(3)

Here μ^{max} determines the maximum growth rate, and x_1^{max} is the maximal bacteria concentration due to environmental constraints. The condition $x_2(0)$ allows to quantify the initial physiological state of the cells and, hence, the process of adjustment (lag-phaselag phase) [21]. To account for the influence of the temperature on the activity of the model, we will use the 'square root' "square root" or Ratkowsky-type model for the maximum growth rate [22]

$$\sqrt{\mu^{\text{max}}} = b(T - T^{\text{min}}),\tag{4}$$

where b is the regression coefficient, and T^{\min} is the minimum temperature at which the growth can occur. As the observable, we choose the bacterial count, i.e.:

$$y(t) = x_1(t) + \epsilon(t), \tag{5}$$

a common choice in predictive microbiology.

The Eqs. Equations 3–5 fully define the system. Here x_1^{max} , b, T^{min} are the parameters that we estimate using observational data y at measurement times t, and temperature T is an input of the system. Based on this model, we would like to optimize the choice of measurement times as well as temperatures (inputs) of the system to find the optimal experimental design.

3.1.2 Code

In order to be able to solve the equations numerically, we first need to define the ODE system described by Eq. 1 in python. Next, we determine all numerical values present in the system. We distinguish between time points t_i at which the result of the ODE is evaluated, inputs \mathbf{u} , which alter the behavior of our system (for example, temperature, humidity, etc.), parameters \mathbf{p} , which are the quantities that we want to estimate, and other arguments needed to solve the ODE. Table 1 provides an overview of these quantities and gives corresponding names in the code. In the following, we

will step-by-step step by step explain how to specify all variables needed by using the example of the Baranyi-Roberts model.

Table 1 Summary of user-defined functions and variables

Description	Formula	Code
	f	<pre>def ode_fun(t, x, u, p, ode_args)</pre>
ODE	$\partial \mathbf{f}/\partial \mathbf{x}$	<pre>def ode_dfdx(t, x, u, p, ode_args)</pre>
	$\partial \mathbf{f}/\partial \mathbf{p}$	<pre>def ode_dfdp(t, x, u, p, ode_args)</pre>
Observable	g	def obs_fun(t, x, u, p, ode_args)
Inptional)e	x ₀	х0
Initial time	t_0	t0
Time points	t_i	t
Inputs	u	u
Parameters	p	p
Other arguments		ode_args

First we define the right-hand side of the ODEs, i.e., we need to implement the Baranyi-Roberts model (Eqs. 3–4) into a function as can be seen in Code Sample 2.

```
# The function name can be chosen freely, but the order
    # of required function arguments is fixed by the definition.
    def baranyi_roberts_ode(t, x, u, p, ode_args):
        # Unpack the input vectors x,u,p for easy access
        # of their components
10
        (x1, x2) = x
11
        (Temp, ) = u
        (x_max, b, Temp_min) = p
        # Calculate the maximum growth rate
15
        mu_max = b**2 * (Temp - Temp_min)**2
17
        # Calculate the right hand side of the ODEs, store
        \# it in a list [ ... ] and return it.
19
20
            mu_max * (x2/(x2 + 1)) * (1 - x1/x_max) * x1,
21
            mu_max * x2
22
        ]
```

Code Sample 2: Definition of the Baranyi-Roberts ODE model -

3.2 Parameter Estimation

After defining the model, the user needs to provide an initial parameter set. This could be chosen from the literature or estimated from previously gathered experimental data. It is common to assume that the observational or measurement noise is Gaussian white noise (e.g., no temporal correlations) with zero mean and variance $\sigma^2(t)$: $\epsilon(t) \sim N(0, \sigma^2(t))$, $\forall t$ [23]. In this case the logarithm of the likelihood function (log-likelihood) is given by Eq. 6:

$$\ln L(\mathbf{p}) \propto -\sum_{i} \frac{\left(\mathbf{g}^{i}(\mathbf{p}) - \mathbf{d}^{i}\right)^{2}}{2\sigma_{i}^{2}}.$$
 (6)

Here we introduced the following shorthand notations:

- \mathbf{d}^i : $\frac{\mathbf{data}}{\mathbf{data}}$ Data measured at time $t = t_i$.
- $\mathbf{g}^{i}(\mathbf{p})$: the The observation function depending on the parameter vector \mathbf{p} evaluated at time $t = t_{i}$.
- σ_i^2 : variance Variance of the observational noise at time $t = t_i$.

The method of maximum likelihood consists in searching for the parameter vector **p** which that maximizes the (log-)likelihood [24].

3.3 Experimental Design

Following our definition of the model and setting the initial parameter vector \mathbf{p}_{0} , we can proceed with experimental design. In essence, experimental design comprises maximizing an objective function depending on the model, the initial parameter vector \mathbf{p}_{0} , external input \mathbf{u} into the system, and a set of discrete observation times t_{i} at which the potential measurements should be performed. The objective function needs to quantify the information the observation \mathbf{y} has about the parameter vector \mathbf{p} . A common choice here is constructing objective functions based on the Fisher information matrix (FIM) [25]. According to the so-called 'Cramer-Rao inequality', the Fisher information is inversely proportional to the minimal squared estimation error [26]. This relation justifies using the FIM to improve our experimental design. In the following we explain one of the ways to calculate the FIM for an ODE system (Eq. 1) and the observable function (Eq. 2) [25].

3.3.1 Sensitivity Calculation

An easy way to calculate the FIM uses local sensitivities of the observables \mathbf{y} , that are in turn calculated from local sensitivities of the internal variables \mathbf{x} [12, 27]. Assume that functions \mathbf{f} and \mathbf{g} are differentiable functions with respect to the state variables \mathbf{x} and parameters \mathbf{p} . The local sensitivities of i-component of the vector \mathbf{x} w.r.t. j-component of the parameter vector are defined by $s_{ij}^x = (\mathrm{d}x_i/\mathrm{d}p_j)$. These can be calculated using an enhanced system

of the ODEs:

$$\begin{cases} \dot{x}_i(t) = f_i(t, \mathbf{x}, \mathbf{u}, \mathbf{p}) \\ \dot{s}_{ij}^x = \sum_k \frac{\partial f_i}{\partial x_k} s_{kj}^x + \frac{\partial f_i}{\partial p_i}. \end{cases}$$
(7)

For the FIM we need the sensitivities of observable functions $(dy_i/dp_j) = s_{ij}$. We determine these at the certain times t_m and input u_n using the solutions of s_{ij}^x :

$$s_{ij}(t_m, u_n) = \sum_{k} \frac{\partial g_i}{\partial x_k} \bigg|_{t_m, u_n} s_{kj}^{x}(t_m, u_n) + \frac{\partial g_i}{\partial p_j} \bigg|_{t_m, u_n}.$$
 (8)

These sensitivities are the elements of the sensitivity matrix [28]. For example, in case of two observables $\mathbf{y} = (y_1, y_2)$, two different inputs $\mathbf{u} = (u_1, u_2)$, N different measurement times, and N_p parameters, sensitivity matrix reads:

$$S = \begin{pmatrix} s_{11}(t_{1}, u_{1}) & \dots & s_{1N_{p}}(t_{1}, u_{1}) \\ \vdots & & \vdots \\ s_{11}(t_{N}, u_{1}) & \dots & s_{1N_{p}}(t_{N}, u_{1}) \\ s_{11}(t_{1}, u_{2}) & \dots & s_{1N_{p}}(t_{1}, u_{2}) \\ \vdots & & \vdots \\ s_{11}(t_{N}, u_{2}) & \dots & s_{1N_{p}}(t_{N}, u_{2}) \\ s_{21}(t_{1}, u_{1}) & \dots & s_{2N_{p}}(t_{1}, u_{1}) \\ \vdots & & \vdots \\ s_{21}(t_{N}, u_{1}) & \dots & s_{2N_{p}}(t_{N}, u_{1}) \\ s_{21}(t_{1}, u_{2}) & \dots & s_{2N_{p}}(t_{1}, u_{2}) \\ \vdots & & \vdots \\ s_{21}(t_{N}, u_{2}) & \dots & s_{2N_{p}}(t_{N}, u_{2}) \end{pmatrix}$$

$$(9)$$

This matrix will be used to directly calculate the FIM:

$$F = S^T Q^{-1} S. (10)$$

Here, Q is the covariance matrix of measurement error [29, 30]. If the measurements are independent, then only the diagonal elements of the matrix are non-zero nonzero:

$$Q = \begin{pmatrix} \sigma_1^2(t_1, u_1) & 0 & 0 & \dots & 0 \\ 0 & \sigma_1^2(t_2, u_1) & 0 & \dots & 0 \\ 0 & 0 & \sigma_1^2(t_1, u_2) & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & \sigma_2^2(t_N, u_2) \end{pmatrix}, \tag{11}$$

where $\sigma_i^2(t_m, u_n)$ is the error of the measurements of observable y_i at time point t_m with input u_n . The error can be either estimated from data or approximated by some error model. For example, one may consider that the error contribution consists of an absolute part that stays constant and a relative part that is proportional to the observable values. Then the diagonal elements of the covariance matrix take form:

$$\sigma_i^2(t_m, u_n) = \gamma_{\text{abs}} + \gamma_{\text{rel}} \cdot y_i(t_m, u_n), \tag{12}$$

where γ_{abs} and γ_{rel} are the coefficients determining the absolute and the relative error contribution, respectively.

In the case the parameters are of very different scale (e.g., on the second and on the day scale), it may be advisable to use the relative or normalized sensitivities to improve not the absolute but the relative accuracy of the parameter estimates:

$$\tilde{s}_{ij}(t_m, u_n) = \frac{\mathrm{d}\ln(y_i)}{\mathrm{d}\ln(p_j)} = \frac{\mathrm{d}y_i}{\mathrm{d}p_j} \frac{p_j}{y_i} \bigg|_{t_m, u_n}.$$
 (13)

In this instance, one needs to use relative measurements measurement errors for the matrix Q:

$$\tilde{\sigma}_i^2(t_m, u_n) = \frac{\sigma_i^2(t_m, u_n)}{y_i^2(t_m, u_n)}.$$
 (14)

3.3.2 Numerical Sensitivity Calculation

For the calculation of the sensitivities $(\text{Eq.}\,7)_z$ we need to supply the derivatives of f with respect to the parameters and state variables. We define $\mathbf{x}=(x_1,x_2,x_3)$ and $\mathbf{p}=(p_1,p_2,p_3)$ with $p_1=x_1^{\max},\ p_2=b$ and $p_3=T^{\min}$. Firstly, we calculate the mathematical derivatives $\partial f_i/\partial p_j$ and $\partial f_i/\partial x_j$ and then implement the corresponding functions. The first component of the Baranyi-Roberts model reads:

$$\dot{x}_1(t) = f_1(t, \mathbf{x}, \mathbf{u}, \mathbf{p}) = \mu^{\max} \frac{x_2(t)}{x_2(t) + 1} \left(1 - \frac{x_1(t)}{x_1^{\max}} \right) x_1(t), \quad (15)$$

where $\sqrt{\mu^{\text{max}}} = b(T - T^{\text{min}})$. It follows:

$$\frac{\partial \mu^{\text{max}}}{\partial p_1} = 0 \tag{16}$$

$$\frac{\partial \mu^{\text{max}}}{\partial p_2} = 2b(T - T^{\text{min}})^2 = \frac{2\mu^{\text{max}}}{b}$$
 (17)

$$\frac{\partial \mu^{\max}}{\partial p_3} = -2b^2(T - T^{\min}) = -\frac{2\mu^{\max}}{T - T^{\min}}$$
 (18)

and consequently:

$$\frac{\partial f_1}{\partial p_1}(t) = \mu^{\text{max}} \qquad \frac{x_2(t)}{x_2(t) + 1} \qquad \frac{x_1(t)}{\left(x_1^{\text{max}}\right)^2} x_1(t)$$
 (19)

$$\frac{\partial f_1}{\partial p_2}(t) = \frac{2\mu^{\text{max}}}{b} \qquad \frac{x_2(t)}{x_2(t) + 1} \left(1 - \frac{x_1(t)}{x_1^{\text{max}}}\right) x_1(t) \tag{20}$$

$$\frac{\partial f_1}{\partial p_3}(t) = -\frac{2\mu^{\max}}{T - T^{\min}} \frac{x_2(t)}{x_2(t) + 1} \left(1 - \frac{x_1(t)}{x_1^{\max}}\right) x_1(t). \tag{21}$$

Similarly, the derivatives $\partial f/\partial x_i$ are given by :-

$$\frac{\partial f_1}{\partial x_1}(t) = \mu^{\text{max}} \quad \frac{x_2(t)}{x_2(t) + 1} \left(1 - 2 \frac{x_1(t)}{x_1^{\text{max}}} \right) \tag{22}$$

$$\frac{\partial f_1}{\partial x_2}(t) = \mu^{\max} \frac{1}{(x_2(t) + 1)^2} \left(1 - \frac{x_1(t)}{x_1^{\max}} \right) x_1(t). \tag{23}$$

The readers are encouraged to calculate the components $\partial f_2/\partial p_i$ and $\partial f_2/\partial x_i$ as an exercise. The resulting implemented functions in python can be seen in Code Sample 3.

Code Sample 3: Derivatives of the function f of the Baranyi-Roberts model ODE $\overline{}$.

3.3.3 Define numerical values Numerical Values

After the definition of the structure of the ODEs, we need to specify numerical values. It is good practice to gather such definitions in the __main__ method of the python program as it was done in Code Sample 4. We start by defining the parameters of the ODEs (line 64) and afterwards afterward the initial values (line 67). Next, we constrain the optimization routine to find the best possible time points in the interval $t_i \in [t_{low}, t_{high}]$. For the purpose we write the times as a dictionary with entries {"lb":t_low, "ub":t_high, "n":n_times}, where "lb" and "ub" are the lower and the upper bound, while n describes

the number of discrete time points at which we want to sample the system (line 70). In contrast, if we wanted to specify explicit values for the sampling points, we would have needed to supply a list of time values or a np.ndarray directly. One can see this approach in lines 78–80 of the code example. Here, we supply an np.ndarray with explicit values, thus fixing the sampling points for the optimization routine.

```
if __name__ == "__main__":
        # Define parameters
63
        p = (2e4, 0.02, -5.5)
64
65
        # Define initial conditions
        x0 = np.array([50, 1])
67
        # Define interval and number of sampling points for times
69
        times = {"lb":0.0, "ub":100.0, "n":2}
        # Define explicit temperature points
        Temp_low = 2.0
73
        Temp_high = 12.0
75
        n_Temp = 2
        # Summarize all input definitions in list (only temperatures)
        inputs = [
78
            np.linspace(Temp_low, Temp_high, n_Temp)
```

Code Sample 4: The main function will encompass every step in our experimental design approach. In the beginning, we insert the actual values for our model definition —

3.3.4 Defining Explicit Values and Sampling

There are two distinct ways to define inputs of the model. First, one can fix (multiple) explicit values for an input variable

```
inputs = [
          np.linspace(Temp_low, Temp_high, n_Temp)
]
# >>> inputs
# [array([2., 12.])]
```

so that experiment will then be solved for only these values without optimizing them. Secondly Second, one can also optimize inputs of the system. For example, suppose we want to optimize the temperature at which the experiments are performed, which means we let the optimization algorithm pick the optimal temperature points such that the information gathered from the system is

maximized. To sample in the interval (Temp_low, Temp_high) with n_Temp points, the reader can simply write:

```
inputs = [
          {"lb":Temp_low, "ub":Temp_high, "n":n_Temp}

# >>> inputs
# [{'lb': 2.0, 'ub': 12.0, 'n': 2}]
```

The difference between choosing explicit values and specifying a sampling range may be subtle at first glance —but in turn allows to very easily switch between fixed values and optimized sampling points.

The different variables can be treated individually as needed. Suppose, we have a system with temperatures and humidity as input variables. We could decide to have the temperature optimized, but fix the humidity explicitly, because experimentally one can change the temperature continuously (or in discrete steps) but is restricted regarding the humidity. In our code, we simply would mix explicit and sampled definitions for individual inputs:

```
inputs = [
    # These values will be sampled
    {"lb":Temp_low, "ub":Temp_high, "n":n_Temp};
    # These are fixed
    np.array([0.4, 0.45, 0.5, 0.55])
]
```

3.3.5 Define Model

After we have decided on the numerical values for our model, we need to put everything together. The FisherModel class serves as the entry point. Here, we simply supply every previously made definition of variables and methods (see **Note** 1).

```
# Create the FisherModel which serves as the entry point
    # for the solving and optimization algorithms
83
    fsm = FisherModel(
84
        ode_x0=x0,
85
        ode_t0=0.0,
86
        ode_fun=baranyi_roberts_ode,
87
        ode_dfdx=ode_dfdx,
88
        ode_dfdp=ode_dfdp,
        times=times,
90
        inputs=inputs,
        parameters=p
92
93
```

Code Sample 5: Define the full model -

For a full list of optional arguments, we refer to the documentation of the package.

3.3.6 Optimality Criteria

In the next step we choose the objective function also called optimality criterion. Optimization of the different objectives leads to different experimental design outcomes. The most popular criteria are [3, 31, 32]:

- **D-optimality criterion** maximizes the determinant det(*F*) of the FIM. Translated to the parameter space, it means that the volume of the confidence region (see Fig. 2) (or the geometric mean of all errors) is minimized. The size of the confidence region is determined by a confidence level, which is typically chosen 90% or 95%. The confidence level can be interpreted as a probability value that the best parameter fit will belong to this area in case of repeating the experiment and estimations multiple times. The confidence region is usually presented as a confidence ellipsoid. D-optimality is the most widely used criterion and is suitable even in case of such parameter transformations as rescaling.
- **E-optimality criterion** maximizes the smallest eigenvalue λ_{min} of the FIM, which is the same as reducing only the largest estimation error.
- **A-optimality criterion** maximizes the sum of all eigenvalues $\sum_{i} \lambda_{i}$, which can be interpreted as minimizing the algebraic mean of all errors.
- Modified E-optimality criterion maximizes the ratio between the minimal and maximal eigenvalue eigenvalues $\lambda_{min}/\lambda_{max}$ and reduces correlation between two parameters corresponding to these eigenvalues.

Fig. 2 The confidence ellipsoid projection to the (p_1, p_2) parameter space. The ellipsoid shows the geometrical meaning of the optimality criteria. The center of the ellipsoid represents the estimated parameter values. The radii are the uncertainties of the estimates associated with different eigenvalues of the FIM λ_1 , λ_2 , $(\lambda_1 < \lambda_2)$. The D-optimality aims to minimize the volume of the ellipsoid, the E-optimality minimizes the largest radius, A-optimality minimizes the perimeter of the rectangle that encloses the ellipse (dashed gray line), and, finally, modified E-optimality tends to make the ellipse as spherical as possible

Each of the criteria has its pros and cons, so the reader should have a closer look at the various properties of these criteria, for instance, in Franceschini's and Macchietto's paper [7]. The geometrical interpretation of the criteria using the confidence region is shown in Fig. 2.

3.3.7 Optimization

After defining the objective function based on the FIM, the next step is to optimize the chosen optimality criteria. Finding the experimental design corresponds to finding the global maximum of the objective, which can be formulated as an optimal control problem [33]. This problem has been widely studied, and multiple numerical solution algorithms for both local and global optimization were introduced [34–37]. In the supplied toolbox *eDPM*, three methods were implemented: differential evolution, basinhopping, and the so-called "brute force" brute force method. We give in the following a brief summary of the implemented methods. For more information, the reader should turn to the available literature, e.g., [38, 39].

The differential evolution algorithm developed by Storn and Price (1996) [38] is one of the stochastic global optimization methods appropriate for nonlinear dynamic problems. Such types of algorithms have mild computational load, but one cannot be sure that the absolute optimum is reached [3]. This method is rather simple and straightforward, does not require any gradient calculation, and is easy to parallelize. Another advantage is its fast convergence and robustness at numerical optimization [40] (see Note 2).

The second implemented method is basin-hopping developed by David Wales and Jonathan Doye [39]. This iterative algorithm combines Monte Carlo Monte Carlo and local optimization (see Note 3). For a deeper understanding of the Monte Carlo Monte Carlo minimization, the reader can refer to the papers [41, 42].

And lastly, a simple brute force method was implemented as well. It is a grid search algorithm calculating the objective function value at each point of a multidimensional grid in a chosen region. This method is suitable for discrete optimization with a limited number of grid values. However, the downside of this technique is its slowness, inefficiency, and long computational times, noticeable for higher numbers of possible discrete solutions [43]. The papers of Banga et al. et al. [35, 44, 45] list additional information about this topic.

3.3.8 Optimization Code

To run the optimization procedure, the following function can be used:

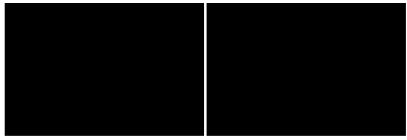

```
fsr = find_optimal(fsm)
```

This code will produce the output shown in Fig. 4 and 5. The user can choose between any of the three previously explained optimization procedures. Any optimization argument of the aforementioned routines can be specified. The default arguments of the "scipy_differential_evolution" optimization method are given by the scipy default arguments [46]. For our specific use-caseuse case, we advise to experiment with the options presented in Code Sample 6. A full list of optional arguments

```
fsr = find_optimal(
         # Required argument: The model to optimize
97
98
         # The optimization method
99
         optimization_strategy="scipy_differential_evolution",
100
         # Our custom options
101
         criterion=fisher_determinant,
102
         relative_sensitivities=True,
         # Options from scipy.optimize.differential_evolution
104
         recombination=0.7,
105
         mutation=(0.1, 0.8),
106
         workers=-1,
107
         popsize=10,
108
         polish=False,
109
    )
110
```

Code Sample 6: Define the optimization conditions and calculate the resulting experimental design -

can be seen in the scipy documentation [47]. In addition, there

(a) Experiment 1: $T = 3.5^{\circ}\text{C}$, t = (b) Experiment 2: $T = 12^{\circ}\text{C}$, t = 0h, 100h 0h, 43h, 100h

Fig. 3 The example of the output of the experimental design optimization procedure for the Baranyi-Roberts model (Eqs. 3–5). The line plot presents the model solution for the observable, and the circles determine the time points suggested by experimental design. The optimal design is proposed for one observable that is the total bacterial count of the species x_1 and consists of two time series where samples are stored at temperatures (a) $T_1 = 3.5^{\circ}$ C and (b) $T_2 = 12^{\circ}$ C. The corresponding measurement times are (a) $t_{11} = 100$ h and (b) $t_{21} = 43$ h, $t_{22} = 100$ h. The initial time $t_0 = 0$ is included in the experimental design by definition

Fig. 4 Command-line output of *eDPM* of all parameters, inputs, ODE functions, and initial values needed to run the optimization method

are some interesting optimization options such as the optional arguments relative_sensitivities, criterion, which are responsible for using relative sensitivities and specifying the optimality criterion as explained in the previous section. Please view the full documentation for explanation. The resulting class fsr contains all definitions, optimal experimental setup (see **Note 4**), and information on the optimization process. For the parameter estimation, the initial values $\mathbf{x}(t_0)$ of the system are required.

3.3.9 Identifiability

Before using the optimal experimental design generated in the preceding section, the reader needs to check if the parameters of the system are identifiable, i.e., to examine if it is possible to obtain a unique solution for the parameters from the optimization. It can happen that a subset of the parameters is non-identifiable. The

Fig. 5 Command-line output that summarizes the optimization routine and its results

non-identifiability can be due to the model structure or observables (structural non-identifiability) or insufficient data (practical nonidentifiability) [48–50]. Structural non-identifiability should be avoided as it results in at least one parameter which that cannot be determined. Fortunately, there is a quick and easy way to check whether the system is structural non-identifiable by calculating the rank of the sensitivity matrix [51, 52]. For an identifiable system, the rank should coincide with the number of estimated parameters. This method allows for the analysis of the local structural identifiability for already chosen inputs and times. Hence, we can check if the final result of the optimization routine is able to identify every parameter by this method. This does not replace a systematic inspection of the model, but at least we can validate our results. If a non-identifiability is detected, the structure of the model or the number of measurements does not allow determination of the involved parameters. This means we need to adjust our description and check all supplied parameters for their validity. On the other hand, there are also a priori methods, e.g., using Lie group theory, that only require the model definition [49]. However, due to the extensiveness of the topic, we constrain ourselves to the method discussed above. Practical non-identifiability results in large confidence intervals [23, 51, 53]. Methods such as profile-likelihood profile likelihood [49] are able to test for these cases, but they require experimental data.

3.3.10 Identifiability Code

Using the *eDPM* package, the reader can quite easily check if the resulting experimental design is structurally identifiable. For this, one can call the function that compares the rank of the sensitivity matrix with the number of parameters as in Code Sample 7. The function returns True, if the identifiability condition is reached, and False otherwise. If this test is not passed, the reader should either reconsider the model structure including the definition of parameters or increase the number of numerically optimized measurement conditions (inputs or times). From a mathematical

```
# Check the structural identifiability
check_if_identifiable(fsr)
```

Code Sample 7: Check the identifiability of the optimization result

point of view, we need at least as many measurement points as we have parameters in our system (see **Note 5**).

3.3.11 Plotting, Json, etc.

Our package also provides the option to save results into a Json file and automatically plot results for the ode solutions, observables, and sensitivities (see Code Sample 8).

```
plot_all_observables(fsr)
plot_all_sensitivities(fsr)
json_dump(fsr, "baranyi.json").
```

Code Sample 8: Plot the observables and sensitivities calculated for the OED and save the result in Json format -

3.4 Examples

3.4.1 Baranyi-Roberts Model - Single Model - Single Species

As a summary of this tutorial, we would like to present the resulting output of our package. To this end we study the growth of a bacterial colony consisting of a single species and describe it mathematically using the Baranyi-Roberts model given by Eqs. 3,4. We aim to estimate the parameters of the model and determine optimal measurement conditions. The observable is the bacterial count, i.e., the first component of the state variable vector y = x_1 . As an additional constraint, we need to consider that the available climate chambers can only operate the temperature in the range from 2 to 12 degrees, and the experiment should not take longer than 100 hours. The parameter values and initial values of the system are taken in accordance with the literature [54] and presented in Table 2. To model realistic uncertainties, we choose the error model given by Eq. 12 with $\gamma_{abs} = 0.3$ and $\gamma_{\rm rel} = 0.1$ for all the measurement points. We identify the three parameters of our system by choosing 4-four independent measurement conditions consisting of two temperature-points and two time points temperature points and two time points. In our experimental design optimization routine, we use the D-optimality criterion, relative sensitivities, and the differential evolution optimization method. The resulting OED for the described system is

Fig. 6 Command-line output showing the result of the identifiability check for the experimental design provided in Fig. 3. The output shows that the experimental design gives a structurally identifiable result and allows parameter estimation of the system

presented in Fig. 3, 7. The identifiability test confirms the validity of our model setup (Fig. 6). For the system described abovethe minimal requirements, the minimal requirement for passing the identifiability test is using a setup with at least two temperatures and two measurement times per temperature. The choice of a minimal number of measurement times can also be justified when looking at Fig. 8. Here we see that one measurement time is not enough as the determinant is numerically very close to zero indicating a non-identifiability of this system configuration. Fig. 7 shows that each of the chosen optimal time points corresponds to the maximum of at least one local sensitivity curve. This maximizes the determinant of the Fisher information matrix.

Table 2
The list of the parameters and ODE's initial values that fully define the one-species system described by the Baranyi-Roberts model and "square root" temperature dependence for the maximum growth rate (Eqs. 3, 4)

Variable	Value	Units
n ^{max}	$2 \cdot 10^{4}$	cfu/g
$\overset{b}{\sim}$	0.2	$^{\circ}\mathrm{C}^{-1}\mathrm{h}^{-1/2}$
T^{\min}	-5.5	°C
$x_1(t_0)$	50.0	cfu/g
$x_2(t_0)$	1.0	$\frac{1}{\infty}$

3.4.2 Two-Species Resource Competition

In this example, we discuss a slightly more complicated system and extend the previous example of bacterial growth to a system where two species are present. The species interact by competitive inhibition because they depend on a common nutrient resource. Analogously to the previous example, we denote the concentration of the two different species as x_1 and y_1 , respectively. The system can be described by the following set of ODEs:

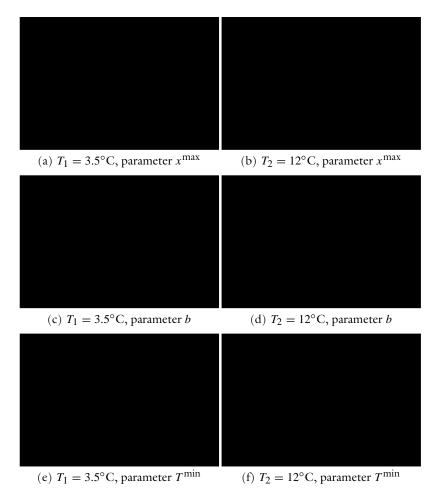

Fig. 7 The example of the sensitivities of the total bacterial count calculated for the experimental design optimization procedure for the Baranyi-Roberts model (Eqs. 3–5). The line plot presents the model solution for the observable, and the circles determine the time points suggested by experimental design. In $(\mathbf{a}, \mathbf{c}, \mathbf{e})$, the sensitivity curves for the experimental series at storage temperature $T_1 = 3.5^{\circ}\mathrm{C}$ are shown for parameters x^{max} , b, T^{min} , respectively. The subfigures $(\mathbf{b}, \mathbf{d}, \mathbf{f})$ present the sensitivities for the $T_2 = 12^{\circ}\mathrm{C}$ experiment for parameters x^{max} , b, T^{min} , respectively

$$\begin{cases} \dot{x}_1 = \alpha_x R x_1 \\ \dot{y}_1 = \alpha_y R y_1 \\ \dot{R} = -\frac{R}{n^{\text{max}}} (\alpha_x x_1 + \alpha_y y_1), \end{cases}$$
 (24)

where α_x , α_y are the time and temperature dependent time and temperature-dependent growth rates for population x_1 , y_1 , and R represents the nutrient pool concentration, respectively. Using the conservation quantity $x_1 + y_1 + n^{\max}R = n^{\max}$, this system can be

Fig. 8 The determinant of the **FIM** as a function of the number of measurement times for the experimental design consisting of two measured temperatures for the Baranyi-Roberts model (Eqs. 3–5)

reduced to :-

$$\begin{cases} \dot{x}_1 = \alpha_x x_1 \left(1 - \frac{x_1 + y_1}{n^{\max}} \right) \\ \dot{y}_1 = \alpha_y y_1 \left(1 - \frac{x_1 + y_1}{n^{\max}} \right). \end{cases}$$
 (25)

Based on the one species one-species case for the growth rates, we use [20, 22]

$$\alpha_x(t,T) = b_x^2 (T - T_x^{\min})^2 \frac{x_2(t)}{x_2(t) + 1}$$
 (26)

$$\alpha_{y}(t,T) = b_{y}^{2}(T - T_{y}^{\min})^{2} \frac{y_{2}(t)}{y_{2}(t) + 1}.$$
 (27)

Combining Eqs. 25 and 27, we get a system of four differential equations:

$$\begin{cases} \dot{x}_{1} = b_{x}^{2} (T - T_{x}^{\min})^{2} \frac{x_{2}}{x_{2}+1} x_{1} (1 - \frac{x_{1} + y_{1}}{n^{\max}}) \\ \dot{x}_{2} = b_{x}^{2} (T - T_{x}^{\min})^{2} x_{2} \\ \dot{y}_{1} = b_{y}^{2} (T - T_{y}^{\min})^{2} \frac{y_{2}}{y_{2}+1} y_{1} (1 - \frac{x_{1} + y_{1}}{n^{\max}}) \\ \dot{y}_{2} = b_{y}^{2} (T - T_{y}^{\min})^{2} y_{2}, \end{cases}$$

$$(28)$$

where x_2 , y_2 are the concentration of the quantities determining the critical substance (nutrient) needed for growth of the species x_1 and y_1 , respectively. The values of the parameter vector $\mathbf{p} = (n^{\max}, b_x, T_x^{\min}, b_y, T_y^{\min})$ and the vector of the initial values $\mathbf{x}(t_0) = (x_1(t_0), x_2(t_0), y_1(t_0), y_2(t_0))$ are presented in Table 3. In comparison to the previous example, we now choose the count of the two bacteria species x_1 , y_1 as observables. Meanwhile, other optimization arguments were taken the same as in the previous example, i.e., we optimize measurement times and temperatures. The new OED is shown in Fig. 9. The presented design shows that the least needed number of experiments is two with temperatures of 2°C and 12°C. In each experiment, two observables that

Fig. 9 The optimal experimental design for the Baranyi-Roberts model with two different species (Eq. 28) is proposed for two observables: the bacterial count of the first species x_1 and of the second species x_2 . (**a**, **c**) show the first experimental series held at the temperature $T_1 = 12^{\circ}\text{C}$ and with measurement times $t_{11} = 12\text{h}$, $t_{12} = 71\text{h}$ for observables x_1 and x_2 , respectively. (**b**, **d**) show the second experimental series held at the temperature $T_2 = 2^{\circ}\text{C}$ and with measurement times $t_{21} = 58\text{h}$, $t_{22} = 90\text{h}$ for observables x_1 and x_2 , respectively. The line plot presents the model solution for the observable, and the circles determine the suggested by experimental design time points. The initial time $t_0 = 0$ is included in the experimental design by definition. (**a**) Species 1, $T = 12^{\circ}\text{C}$, t = 0h, 12h, 71h. (**b**) Species 1, $T = 2^{\circ}\text{C}$, t = 0h, 58h, 90h. (**c**) Species 2, $T = 12^{\circ}\text{C}$, t = 0h, 58h, 90h

correspond to the concentrations of two bacteria types and two time points were measured (see **Note 6**).

Table 3
The list of the parameter and ODE's initial values of the system that fully define the Baranyi-Roberts two-species system (Eq. 28)

Variable	Value	<u>Units</u>
n ^{max}	$2 \cdot 10^4$	cfu/g
b_{x}	0.03	$^{\circ}\mathrm{C}^{-1}\mathrm{h}^{-1/2}$

$y_2(t_0)$	1.0	1

3.5 Conclusion

We introduced the concepts of experimental design and identifiability and their practical applications to systems described by ODEs. In addition, we implemented the numerical calculations in simple python code which we provide within our software *eDPM*. Our toolbox provides a simple way to apply methods of

mathematical statistics and optimization. We demonstrated how to use these methods by applying them to the well-known Baranyi-Roberts model for microbial growth with one and two species. These results show us how parameters of the model can now be estimated most precisely by designing experiments around the predicted measurement conditions. In summary, model-based experimental design can accelerate and simplify the planning of efficient experiments for parameter estimation in microbiology.

4 Notes

- 1. When using the syntax as shown in Code Sample 5, the order of arguments does not matter. However, when only using FisherModel(x0, 0.0, ...), please pay attention to the order of arguments.
- 2. In differential evolution optimization algorithm, an initial population of candidate vectors (sampling times and inputs) is randomly chosen from the region of available values. Then each vector mutates by mixing with one of other candidate vectors: To a chosen vector from the initial population D_0 , we add a weighted difference between two other randomly chosen vectors from the same set $(D_{rand1} - D_{rand2})$. A new mutated vector D_m is obtained. The next step is to construct a new trial solution. This is done by choosing the elements of the trial vector either from the initial D_0 or from the mutated D_m vectors. For each new element of the trial vector, a random number is drawn uniformly from the interval [0, 1) and compared to the so-called recombination constant. If this random number is less than the recombination constant, then the trial vector element is chosen from the vector D_m , otherwise from D_0 . The degree of mutation can be controlled by changing the recombination constant; the larger this constant is, the more often vector elements are chosen from D_m . Subsequently, the objective function is calculated using the trial vector, and the result is compared to result obtained using the initial solution D_0 ; and the best of them is chosen for the next generation. This procedure is repeated for every solution candidate of the initial population, by means of which the new generation is build built [46]. The process of population mutation is repeated till a stopping criterion is reached, e.g., the maximum number of generations (steps) is reached or the standard deviation of the candidate vectors is below a certain threshold [55].
- 3. During the iteration step, the design vector, i.e., vector of measurement times and inputs, is subject to a random perturbation and then to local minimization. After this, the step is either

- accepted or rejected. As in a standard Monte Carlo Monte Carlo method, the decision is made using the Metropolis criterion for the objective function [56].
- 4. Our toolbox optimizes and provides the optimal experimental timepoints time points with an assumption that the initial one t_0 is always measured. Hence, the reader should keep that in mind and include the initial time t_0 as a measurement point in the final OED.
- 5. The provided identifiability test only allows to exclude structural identifiability, but to obtain reasonable confidence intervals for parameter estimates the practical identifiability should be considered as well. Therefore, in reality more experiments are needed to increase the accuracy of the model. Thus, we suggest that the reader considers the optimization result not as a finished design but as a reference pointing to the minimal requirements and the most crucial conditions (inputs and times) for the parameter estimations.
- 6. For both temperatures, we require at least two time-points time points for identifiability. Thus, we can estimate the parameters by performing experiments according to this design.
